

Intermediate (Level II) – Q7

In a diving competition, each member of a five-judge panel gives a score, in which the highest and lowest ones are deleted. Then, the remaining three scores are added up and multiplied by the difficulty coefficient of the dive to calculate the athlete's final score.

For instance, if the scores awarded by the five judges are 10, 9, 8, 8.5 and 7, and the difficulty coefficient of the dive is 2, then the athlete's final score is:

$$(9 + 8 + 8.5) \times 2 = 51$$

In the Python program, the list `score` stores the scores awarded by five judges, while the variable `coef` stores the difficulty coefficient of the dive, as well as calculate and display the athlete's final score:

<u>Line</u>	<u>Code</u>
1	<code>score = [10, 9, 8, 8.5, 7]</code>
2	<code>coef = 2</code>

Your Python should be able to

- calculate the sum of the scores awarded by the five judges;
- find the highest (maximum) and lowest (minimum) scores of an athlete awarded by the five judges;
- calculate the athlete's final score.
